The Solar System

The Universe in my pocket

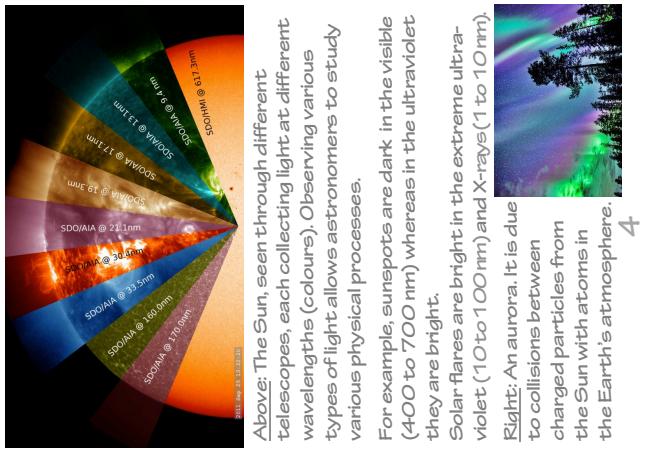

Do these
objects
belong to the
Solar
System?

Quiz

The Sun is only one of the hundreds of thousands of different types of stars in the Milky Way, out there are many different types of stars like our Sun while others are very cold. Some of them are very hot while some are very cold. Some may have planets around them. We can only imagine that many have been discovered so far. The Milky Way is just one of the galaxies that exist in the universe. Thus, how many planets are there in the whole universe? This is a hard question because we have to count all the stars in the universe.

Artist's picture showing a view of the surface of the planet Proxima b discovered around the closest star Proxima Centauri. Our Sun is only one of the hundreds of thousands of different types of stars in the universe. This is a hard question because we have to count all the stars in the universe. Thus, how many planets are there in the whole universe? We can only imagine that many have been discovered so far. The Milky Way is just one of the galaxies that exist in the universe. Thus, how many planets are there in the whole universe? This is a hard question because we have to count all the stars in the universe. There are billions of galaxies in the universe. Some are bright in the extreme ultraviolet and X-ray (10¹⁰-10¹¹ nm) whereas in the visible wavelengths (400-700 nm), they are bright. For example, sunspots are dark in the ultraviolet wavelengths (400-700 nm). Observing various wavelengths (400-700 nm) with telescopes are a part in ultraviolet wavelengths (10¹⁰-10¹¹ nm) whereas in the visible wavelengths (400-700 nm) they are bright. Solar flares are bright in the extreme ultraviolet wavelengths (400-700 nm). Observing various wavelengths (400-700 nm) with telescopes are a part in ultraviolet wavelengths (10¹⁰-10¹¹ nm) whereas in the visible wavelengths (400-700 nm) they are bright.

Above: The Sun, seen through different telescopes, each collecting light of different wavelengths (colours). Observing various wavelengths (400-700 nm) with telescopes are a part in ultraviolet wavelengths (10¹⁰-10¹¹ nm) whereas in the visible wavelengths (400-700 nm) they are bright. For example, sunspots are dark in the ultraviolet wavelengths (400-700 nm) whereas in the visible wavelengths (400-700 nm) they are bright. Solar flares are bright in the extreme ultraviolet wavelengths (400-700 nm) whereas in the visible wavelengths (400-700 nm) they are bright. The Earth's atmosphere from the Sun is due to solar flares are bright in the extreme ultraviolet wavelengths (400-700 nm) whereas in the visible wavelengths (400-700 nm) they are bright.

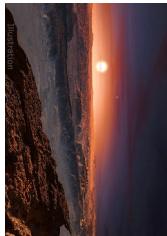

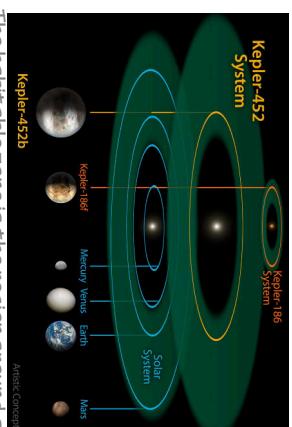

The Sun

The Sun is a star. It lies at the center of the Solar System and contains 99.9% of its mass.

The Sun is an average-mass star. The biggest stars have masses one hundred times larger, while the smallest ones have masses ten times smaller.

All the heat and light that we receive from the Sun come from its nucleus where the fusion of hydrogen is occurring. The temperature at the center of the Sun is 15 million degrees Celsius.

The magnetic field of the Sun causes a variety of phenomena such as sun spots, flares, storms, and the beautiful auroras occurring on Earth.

Artist's picture showing a view of the surface of the planet Proxima b discovered around the closest star Proxima Centauri.

The habitable zone is the region around a star where liquid water can exist on the surface of a planet (because the temperature is neither too high nor too low). The green belts in the image above show the habitable zones in some recently discovered planetary systems.

8

Left: Ceres is the biggest asteroid in the Main Asteroid Belt and a dwarf planet. The image shows the enigmatic bright spots on its surface.

Right: Philae was the first instrument that landed on a comet, 67P/Churyumov-Gerasimenko.

-Asteroids are rocks that orbit the Sun. Their sizes range from one to 950 kilometers. They are mostly found in a ring between Mars and Jupiter, called the main asteroid belt.

-Comets are balls of ice and dust that arise from the Kuiper Belt and from the Oort Cloud. Occasionally comets approach the Sun, which melts them. One of the most famous comets is Halley's Comet, which visits us every 75 years.

-Meteoroids are rocks that travel through the solar system. If they enter Earth's atmosphere they are called **meteors**, or shooting stars. If they survive to reach the surface of the Earth, they are called **meteorites**.

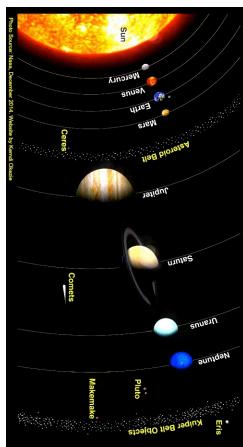

-Moons are bodies that orbit planets or dwarf planets.

9

Left: The meteorite 'La Concepción'. It weighs more than 3 tons. It is exhibited in the Institute of Astronomy in Mexico City.

10

The Solar System is composed of the Sun and of all the bodies travelling around it: planets, dwarf planets, moons, asteroids, comets, meteors... .

Almost 25 objects in the Solar System have sizes bigger than 1000 kilometers, the Sun, the four gaseous planets and the four earth-like planets, five dwarf planets, and around 12 moons and trans-neptunian objects.

The other constituents (asteroids, and dust particles) are much smaller.

The planets

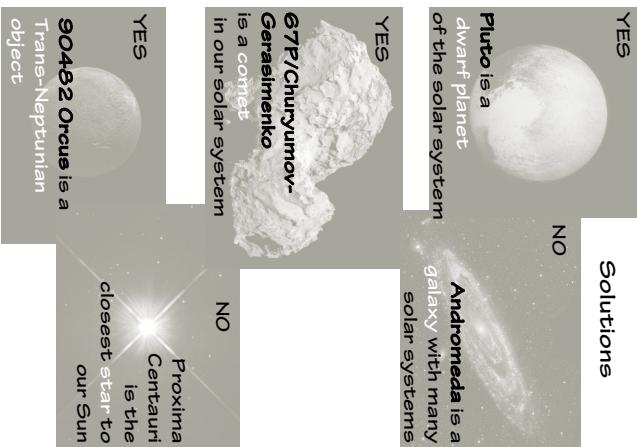

The first official definition of a planet was given only in August, 2006 by the International Astronomical Union (IAU). With this definition **Pluto** 'stopped' being the ninth planet.

A planet is a body that:

- 1) orbits the Sun,
- 2) has enough mass to be rounded by its own gravity, and
- 3) has cleared its neighborhood of minor objects.

Objects that satisfy 1) and 2) but

The Solar System contains eight planets; four **earth-like planets** (Mercury, Venus, Earth and Mars) and four **gaseous planets** (Jupiter, Saturn, Uranus, and Neptune). 7

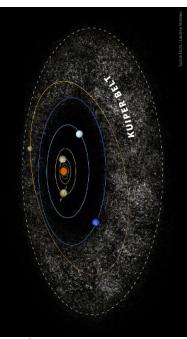

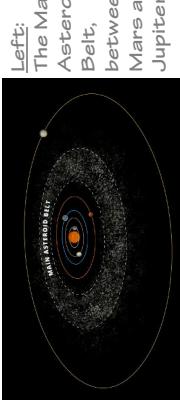

The Universe in my pocket No. 4

This booklet was written in 2016 by Gloria delgado Indreda from the Instituto de Astronomía, UNAM (Mexico) and revised by Stan Kurtz from the Instituto de Radioastronomía y Astrofísica, UNAM (Mexico).

Later, gravity pulled the rest of the material into clumps and rounded some of them, forming the planets and dwarf planets. The leftovers resulted in comets,

The diagram illustrates the scale of the Oort Cloud and the Kuiper Belt relative to the Sun and the inner planets. The Sun is at the center, with the Earth and Mars shown in their orbits. A red elliptical ring represents the Kuiper Belt, extending from approximately 30 AU to 50 AU. A much larger, translucent sphere represents the Oort Cloud, extending from about 5,000 AU to 100,000 AU. A yellow arrow points from the text "The Oort Cloud 5,000-100,000 A.U." to the outer boundary of the Oort Cloud sphere. Another yellow arrow points from the text "Kuiper belt" to the inner boundary of the red Kuiper Belt ring. The label "Sun" is placed near the center of the Sun's image.

Zones in the Solar System

The Main Asteroid Belt contains billions of asteroids. These bodies formed at the beginning of the Solar System and were trapped in this annular region by Jupiter's gravity.

The Kuiper Belt contains hundreds of thousands of comets and other bodies, such as Pluto.

The Oort Cloud is a cloud of small bodies at the edge of the Solar System. It is so far away from us

and so big that Voyager 1 (a spacecraft launched in 1977) will take hundreds of years to reach it, and thousands of years to leave it. At the speed of the light (300,000 kilometers per second), it takes one year to travel from the Sun to the Oort Cloud.

Formation of the Solar System

Our Solar System formed around 4600 million years ago. We know this from the study of meteorites and radioactivity.

It all began with a cloud of gas and dust. A nearby supernova explosion probably perturbed the calm cloud, which then started to contract due to gravity, forming a flat, rotating disk with most of the material concentrated in the center: the protosun.

Later, gravity pulled the rest of the material into clumps and rounded some of them, forming the planets and dwarf planets. The leftovers resulted in comets, asteroids, and meteoroids.
